Objective: The goal of this study is to assess the cosmetic, functional and tensile strength parameters of a novel, stapler-based subcutaneous bioabsorbable skin closure system, in a porcine model.

Description and Method of Use: A

disposable stapler system, preloaded with uniquely shaped bioabsorbable staples, has been developed to close various length skin incisions, including laparoscopic incisions. The "SubQ It!" stapler exploits a design geometry chosen to permit excellent visibility for the surgeon to precisely control placement of the staple, especially important in closing small 7-10 mm incisions. Once the surgeon positions the two sides of the tissue in the foot of the stapler, pressing the plunger delivers a staple which has two barbed legs connected by a flexible "bridge". The barbs engage and the bridge holds the two tissue edges together with excellent tensile strength and security. The resulting level of tissue edge apposition and eversion is designed to permit excellent first intention healing.

Animal Study: The SubQ It! skin closure system was assessed in seven (7) domestic swine (35-40 kg) using a published and

standardized porcine skin incision wound healing model. All animal and procedural activities

were approved by The Dartmouth College Institutional Animal Care and Use Committee (IACUC) and conducted in full USDA/OLAW and FDA-GLP compliance. The Dartmouth College Animal

Care and Use Program and related facilities are fully accredited by the American Association for the Accreditation of Laboratory Animal Care (AAALAC). Standard cutaneous incisions, 1cm, 2cm

and 7cm in length, made by a board-certified surgeon, were closed by the SubQ It! device. For comparative purposes, a single 7cm incision in the same animal was closed using a commercially available subcutaneous suture device (INSORB® Absorbable Skin Stapler, Incisive Surgical, Inc.). Healing in the 1cm and 2cm incisions (which are too short to apply the INSORB device) was assessed by histology, clinical observation, photographs, and tensile strength tests.

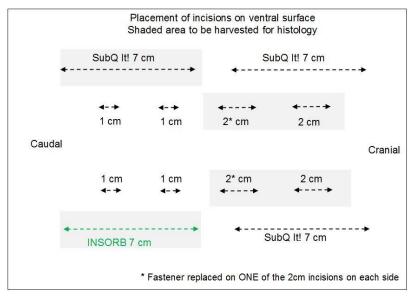

Figure 3. Incision Plan for each animal

Results: Incisions were allowed to heal for 3, 7, 10, 20, 30, 60 or 90 days. All incisions healed without complications and with minimal scarring. Except for very slight redness at the 3 day endpoint, the incision sites were devoid of erythema, swelling, heat, inflammation and dehiscence. Results presented in Figures 4 – 9 represent three separate evaluations:

(1) Clinical evaluation of all wounds, by veterinarian and study director at end dates of 3,7,10, 20, 30, 60, and 90 days post-surgery.

(2) Photographs of the 7cm incisions closed with either Control or Test device were taken at end dates of 3,7,10, 20, 30, 60, and 90 days post-surgery, matched with the corresponding photographs from the respective day of surgery, and read by a board certified veterinary dermatologist, blinded as to the device used and the duration of healing.

(3) Full thickness tissue samples were taken at each endpoint for histological assessment by a board certified veterinary pathologist blinded as to the device used and the duration of healing.

Finally fasteners were recovered from animals at 3, 7, 10 and 20 days and tested for residual tensile strength. It is known that the fastener material degrades by hydrolysis and tensile strength is lost over time. The purpose of these measurements was to ensure that tensile strength of the test fastener in vivo is maintained through 20 days to provide adequate support, including safety margin, until incisional healing can provide the needed strength without the fasteners. Tensile strength measurements decreased from 10 N to 8 N from non-implanted controls to day-20 *in vivo* fasteners. On the average, residual strength was 82 percent of initial strength, and significantly stronger than the minimum acceptable 2 Newtons.

Figure 4 shows the results of examining the 7 cm incision sites using visual inspection and manual palpation for Control (INSORB) and Test (SubQ It!) devices. Both Wound Description assessments (erythema, swelling, gaping, along with manual palpation of the incisions for nodules) and Cosmetic Appearance (scoring for borders, contour, margins, edges and distortion of the incision) using the Hollander Wound Evaluation Scale (HWES) showed no significant difference between Test and Control devices.

Figure 5 shows cosmetic evaluation (wound borders, contour, margins, edges and distortion) of photographs indicating good cosmetic healing in both Test and Control incisions. Incisions on days 3, 7, 10, 60 and 90 exhibited some degree of either edge inversion or margin separation, which decreased the total cosmetic score in both Test and Control groups. Day 3 and 7 incisions closed with the Test device achieved slightly better scores than the Control device but these would not be clinically significant.

Figure 6 shows the total scores combining acute inflammatory reaction, tissue edema hemorrhage, necrosis, new vessels, granulation tissue formation, persistent inflammation and fibrosis. Individually and combined, there was no significant difference between Test and Control devices.

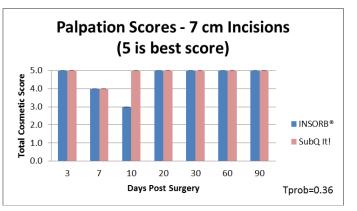

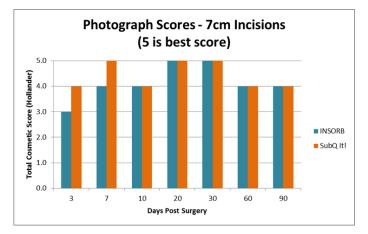

Figure 4. Hollander scores for the Control and the Test incisions based on manual palpation

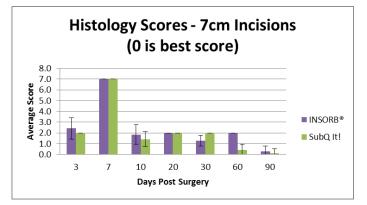

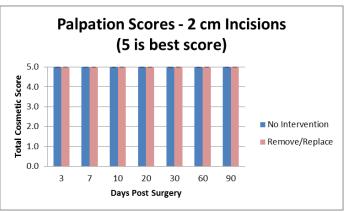

Figure 6. Total scores from histopathology evaluations of H&E sections

As part of the FDA recommended protocol, incisions in which the SubQ It! fastener was removed/replaced were compared to incisions without such intervention. For comparison four (4) incisions, two with intervention and two without, each 2 cm long were compared on each animal (28 incisions total). Figure 7 demonstrates the clinical evaluation using visual and manual palpation of the incisions blinded as to intervention. The "No Intervention" group did not have a staple removed. The "Remove/Replace group had one staple removed /replaced per incision at the time of surgical closure. There were no differences noted and all wounds demonstrated optimal healing.

Figure 8 shows the evaluation of photographs of the wounds with and without the staple removal procedure. No significant difference was seen in the HWES scores (p =0 .60).

Figure 9 shows the results of histopathology evaluation of the 2cm incisions with and without fastener removal. All readings were blinded as to the intervention and duration of healing. Scores shown are totals of individual readings of acute inflammatory reaction, tissue edema hemorrhage, necrosis, new vessels, granulation tissue formation, persistent inflammation and fibrosis, where 0 is the absence of such characteristics. There is a slight increase in scores for the group which had a fastener removed and replaced, as might be expected as this is one of two fasteners in a very small incision. The difference was not significant (p =0.22).

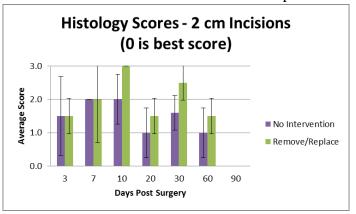

Figure 9. Total scores from histopathology evaluations of 2cm incisions with fastener removal/replaced

Conclusions: Satisfactory wound closures were obtained for the new device on all sized incisions tested. SubQ It! stapler performance was substantially equivalent on 7 cm incisions in all respects to the control device.
